

Beyond GDP? Welfare across Countries and Time[†]

By CHARLES I. JONES AND PETER J. KLENOW*

We propose a summary statistic for the economic well-being of people in a country. Our measure incorporates consumption, leisure, mortality, and inequality, first for a narrow set of countries using detailed micro data, and then more broadly using multi-country datasets. While welfare is highly correlated with GDP per capita, deviations are often large. Western Europe looks considerably closer to the United States, emerging Asia has not caught up as much, and many developing countries are further behind. Each component we introduce plays a significant role in accounting for these differences, with mortality being most important. (JEL D63, E21, E23, E24, I12, O57)

As many economists have noted, GDP is a flawed measure of economic welfare. Leisure, inequality, mortality, morbidity, crime, and the natural environment are just some of the major factors affecting living standards within a country that are incorporated imperfectly, if at all, in GDP. The Stiglitz Commission Report (Stiglitz, Sen, and Fitoussi 2009) was the latest attempt to sort through the criticisms of GDP and seek practical recommendations for improvement. Though there are significant conceptual and empirical hurdles to including some of these factors in a welfare measure, standard economic analysis is arguably well-equipped to deal with several of them.

We propose a simple summary statistic for the welfare of a country's population, measured as a consumption equivalent, and compute its level and growth rate for a diverse set of countries. This welfare measure combines data on consumption, leisure, inequality, and mortality using the standard economics of expected utility. The focus on consumption-equivalent welfare follows in the tradition of Lucas (1987), who calculated the welfare benefits of eliminating business cycles versus raising the growth rate.

As an example, suppose we wish to compare living standards in France and the United States. GDP per person is markedly lower in France: France had a per capita

We are grateful to Mark Aguiar, Romans Pancs, Luigi Pistaferri, David Romer, David Weil, Alwyn Young, and many seminar participants for helpful comments, to David Laibson for a conversation that inspired this project, and to Gabriela Calderon, Siddharth Kothari, Jihee Kim, Huiyu Li, Alejandro Molnar, Ariana Poursartip, Rui Xu, and Zhen (Zachary) Yan for excellent research assistance. The authors declare that they have no relevant or material financial interests that relate to the research described in this paper.

[†]Go to <http://dx.doi.org/10.1257/aer.201110236> to visit the article page for additional materials and author disclosure statement(s).

GDP in 2005 equal to just 67 percent of the US value. Consumption per person in France was even lower—only 60 percent of the United States, even adding government consumption to private consumption. However, other indicators looked better in France. Life expectancy at birth was around 80 years in France versus 77 years in the United States. Leisure was higher in France: Americans worked 877 hours (per person, not per worker) versus only 535 hours for the French. Inequality was substantially lower in France: the standard deviation of log consumption was around 0.54 in the United States but only 0.42 in France.

Our welfare metric combines each of these factors with the level of consumption using an expected utility framework. We do this in two ways. First, we use detailed micro data from household surveys for 13 countries to provide a measure of welfare with as few assumptions as possible. Then, we use publicly available multi-country datasets to construct cruder welfare measures for 152 countries. Cross-checking these “macro” results with the detailed “micro” results suggests that there is valuable information even using the coarse multi-country datasets.

Our consumption-equivalent measure aims to answer questions such as: what proportion of consumption in the United States, given the US values of leisure, mortality, and inequality, would deliver the same expected utility as the values in France? In our results, lower mortality, lower inequality, and higher leisure each add roughly 10 percentage points to French welfare in terms of equivalent consumption. Rather than looking like 60 percent of the US value, as it does based solely on consumption, France ends up with consumption-equivalent welfare equal to 92 percent of that in the United States.¹

The French example applies more broadly to Western Europe as a whole, but for the poorer countries of the world, the opposite is typically true. Because of lower life expectancy and higher inequality, their consumption equivalent welfare is often less than their income: Western Europe is closer to the United States, but poor and middle-income countries are typically further behind. More generally, our findings can be summarized as follows:

- (i) GDP per person is an informative indicator of welfare across a broad range of countries: the two measures have a correlation of 0.98. Nevertheless, there are economically important differences between GDP per person and consumption-equivalent welfare. Across our 13 countries, the median deviation is around 35 percent—so disparities like we see in France are quite common.
- (ii) Average Western European living standards appear much closer to those in the United States (around 85 percent for welfare versus 67 percent for income) when we take into account Europe’s longer life expectancy, additional leisure time, and lower inequality.
- (iii) Most developing countries—including much of sub-Saharan Africa, Latin America, southern Asia, and China—are substantially poorer than incomes

¹Our calculations do not conflict with Prescott’s (2004) argument that Americans work more than Europeans because of lower marginal tax rates in the United States. The higher leisure in France partially compensates for their lower consumption.

suggest because of a combination of shorter lives and extreme inequality. Lower life expectancy reduces welfare by 15 to 50 percent in the developing countries we examine. Combined with the previous finding, the upshot is that, across countries, welfare inequality appears even greater than income inequality.

- (iv) Growth rates are typically revised upward, with welfare growth averaging 3.1 percent between the 1980s and the mid-2000s versus income growth of 2.1 percent. A boost from rising life expectancy of more than a percentage point shows up throughout the world, with the notable exception of sub-Saharan Africa. When welfare grows 3 percent instead of 2 percent per year, living standards double in 24 years instead of 36 years; over a century, this leads to a 20-fold increase rather than a 7-fold increase.²

The US-France comparison, and our results for other countries, emphasize an important point. High hours worked per capita and a high investment rate are well-known to deliver high GDP per capita, other things being equal. But these strategies have associated costs that are not reflected in GDP. Our welfare measure values the high GDP but adjusts for the lower leisure and lower consumption share to produce a more complete picture of living standards.

This paper builds on a large collection of related work. Nordhaus and Tobin (1972) introduced a “Measure of Economic Welfare” that combines consumption and leisure, values household work, and deducts urban disamenities for the United States over time. We incorporate life expectancy and inequality and make comparisons across countries as well as over time, but we do not attempt to account for urban disamenities. The United Nations Human Development Index combines income, life expectancy, and literacy, first putting each variable on a scale from zero to one and then averaging. In comparison, we combine different ingredients (consumption rather than income, leisure rather than literacy, plus inequality) using a utility function to arrive at a consumption-equivalent welfare measure that can be compared across time for a given country as well as across countries. Ravallion (2012) criticizes “mashup indices” like the Human Development Index for their arbitrary nature; our approach is explicitly grounded in economic theory. Fleurbaey (2009) contains a more comprehensive review of attempts at constructing measures of social welfare.

Becker, Philipson, and Soares (2005) use a utility function to combine income and life expectancy into a full-income measure. Their focus is on the evolution of cross-country dispersion, and their main finding is that dispersion decreases significantly over time when one combines life expectancy with income. Our broader welfare measure includes leisure and inequality as well as life expectancy, and uses consumption instead of income as the base. All of these differences are first-order to our findings. We further emphasize results for individual countries, not just trends in dispersion. Like us, Cordoba and Verdier (2008) carry out Lucas-style calculations, in their case comparing the welfare cost of lifetime consumption inequality within versus across countries.

²Our results reinforce research on welfare gains from rising life expectancy. See Nordhaus (2003), Becker, Philipson, and Soares (2005), Murphy and Topel (2006), and Hall and Jones (2007).

Fleurbaey and Gaulier (2009) construct a full-income measure for 24 OECD countries. Like us, they incorporate life expectancy, leisure, and inequality. Our paper differs in many details, both methodological and empirical. For example, we focus on consumption instead of income, report results for countries at all stages of development, and consider growth rates as well as levels. Boarini, Johansson, and d'Ercole (2006) is another related paper that focuses on OECD countries. They construct a full-income measure by valuing leisure using wages and combining it with per capita GDP. They consider adjusting household income for inequality according to various social welfare functions and, separately, consider differences in social indicators such as life expectancy and social capital. Our approach differs in using expected utility to create a single statistic for living standards in a much larger set of countries.

There are many limitations to the welfare metric we use, and a few deserve special mention at the outset. First, we evaluate the allocations both within and across countries according to one set of preferences. We do consider different functional forms and parameter values in our robustness checks. Second, we do not try to measure morbidity. We use life expectancy as a very imperfect measure of health. Third, we make no account for direct utility benefits from the quality of the natural environment, public safety, or political freedom.

The rest of the paper is organized as follows. Section I lays out the simple theory underlying the calculations. Section II describes the micro data that we use for our main results in Section III. Section IV explores robustness. Section V presents results for a large set of countries using publicly-available macro data. Section VI concludes.

I. Theory

Comparing GDPs across countries requires the use of a common set of prices. Similarly, although people in different countries may have different preferences, we compare welfare across countries using a common specification for preferences. To be concrete, we consider a fictitious person possessing these preferences and call him "Rawls."

Behind the veil of ignorance, Rawls is confronted with a lottery. He will live his entire life in a particular country. He doesn't know whether he will be rich or poor, hardworking or living a life of leisure, or even whether some deadly disease will kill him before he gets a chance to enjoy much of his life. Over his life, he will draw from the cross-sectional distributions of consumption and leisure and from the cross-sectional mortality distribution corresponding to each age in a particular year. What proportion of Rawls' annual consumption living his life in the United States would make him indifferent to living life instead in, say, China or France? Call the answer to this question λ_{China} or λ_{France} . This is a consumption-equivalent measure of the standard of living. In the interest of brevity, we will sometimes call this "welfare," but strictly speaking we mean a consumption-equivalent measure.

A quick note on a possible source of confusion. In naming our individual Rawls we are referencing the veil of ignorance emphasized by Rawls (1971) and Harsanyi (1953). In contrast, we wish to distance ourselves from the maximin social welfare function advocated by Rawls that puts all weight on the least well-off person in society. While that is one possible case we could consider, it is extreme and far from

our benchmark case. As we discuss next, our focus is a utilitarian expected utility calculation giving equal weight to each person.

A. The Main Setup

Let C denote an individual's annual consumption and ℓ denote leisure plus time spent in home production. Expected lifetime utility is then

$$(1) \quad U = E \sum_{a=1}^{100} \beta^a u(C_a, \ell_a) S(a),$$

where $S(a)$ is the probability an individual survives to age a and the expectations operator applies to the uncertainty with respect to consumption and leisure. To implement our welfare calculation, let $U_i(\lambda)$ denote expected lifetime utility in country i if consumption is multiplied by a factor λ at each age,

$$(2) \quad U_i(\lambda) = E_i \sum_{a=1}^{100} \beta^a u(\lambda C_{ai}, \ell_{ai}) S_i(a).$$

By what factor, λ_i , must we adjust Rawls' consumption to make him indifferent between living his life as a random person in the United States and living in some other country i ? The answer to this question satisfies

$$(3) \quad U_{us}(\lambda_i) = U_i(1).$$

The remainder of this paper implements this calculation in a variety of ways, both across countries to compare levels of welfare and over time to compute measures of welfare growth. For each country-year, we use cross-sectional data on consumption and leisure and cross-sectional data on mortality by age, treating individuals as drawing from this cross-section (adding growth) over their lifetime.

B. An Illustrative Example

To see how we implement this calculation, an example is helpful. This example makes strong assumptions to get simple results that are useful for intuition. We will relax many of these assumptions in the next subsection. First, assume that flow utility for Rawls is

$$(4) \quad u(C, \ell) = \bar{u} + \log C + v(\ell),$$

where $v(\ell)$ captures the utility from leisure and home production. Next, suppose that consumption in each country is lognormally distributed across people at a point in time, independent of age and mortality, with arithmetic mean c_i and a variance of log consumption of σ_i^2 . Then $E[\log C] = \log c - \sigma^2/2$. Over time, assume that consumption grows at a constant rate g . Finally, assume for now that leisure is constant across ages and certain. Under these assumptions, expected lifetime utility is given by

$$(5) \quad U_i^{\text{simple}} = \left[\sum_a \beta^a S_i(a) \right] \cdot \left(\bar{u} + \log c_i + v(\ell_i) - \frac{1}{2} \cdot \sigma_i^2 \right) + g \cdot \sum_a \beta^a S_i(a) a.$$

In the special case in which $\beta = 1$ and $g = 0$, the terms involving the survival rates simplify. In particular, $e \equiv \sum_a S(a)$ equals life expectancy at birth, and we have

$$(6) \quad U_i^{simple} = e_i \left(\bar{u} + \log c_i + v(\ell_i) - \frac{1}{2} \cdot \sigma_i^2 \right).$$

That is, lifetime utility is just the product of life expectancy and expected flow utility from each year. In this special case, consumption equivalent welfare in (3) becomes

$$(7) \quad \begin{aligned} \log \lambda_i^{simple} = \frac{e_i - e_{us}}{e_{us}} \left(\bar{u} + \log c_i + v(\ell_i) - \frac{1}{2} \sigma_i^2 \right) & \text{Life expectancy} \\ + \log c_i - \log c_{us} & \text{Consumption} \\ + v(\ell_i) - v(\ell_{us}) & \text{Leisure} \\ - \frac{1}{2} (\sigma_i^2 - \sigma_{us}^2). & \text{Inequality} \end{aligned}$$

This expression provides an additive decomposition of the forces that determine welfare in country i relative to the United States. The first term captures the effect of differences in life expectancy: it is the percentage difference in life expectancy weighted by how much a year of life is worth—the flow utility in country i . The remaining three terms denote the contributions of differences in consumption, leisure, and inequality. At the end of the paper, we will use (7) to compute consumption-equivalent welfare for a large sample of countries using readily available data sources.³

C. Welfare Calculations using Micro Data

While the example above is helpful for intuition, our micro data is much richer, allowing far fewer assumptions. Let the triplet $\{j, a, i\}$ represent individual j of age $a \in \{1, \dots, 100\}$ in country i . Denote the sampling weight on individual j in country i as ω_{ja}^i , and the number of individuals of age a in country i as N_a^i . We make the convenient assumption that the possible levels of consumption and leisure match the levels seen for individuals in the sample in each age group in each country-year. Within each age group, we normalize the sampling weights to sum to 1,

$$(8) \quad \bar{\omega}_{ja}^i \equiv \frac{\omega_{ja}^i}{\sum_{j=1}^{N_a^i} \omega_{ja}^i}.$$

Behind the veil of ignorance, expected utility for Rawls in country i is

$$(9) \quad U_i = \sum_{a=1}^{100} \beta^a S_a^i \sum_{j=1}^{N_a^i} \bar{\omega}_{ja}^i u(c_{ja}^i e^{ga}, \ell_{ja}^i),$$

³This decomposition, and the richer one below using micro data, is not without problems. For example, consumption of healthcare, food, and shelter all influence life expectancy. With better data and a deeper understanding of how life expectancy is produced, one could make better comparisons.

where S_a^i is the probability of surviving to age a in country i . Note that each age group is weighted by country-specific survival rates rather than local population shares. As before, $U_i(\lambda)$ denotes expected utility for Rawls in country i if consumption is reduced by proportion λ in all realizations. Our consumption-equivalent welfare metric λ_i continues to be defined implicitly by $U_{us}(\lambda_i) = U_i(1)$.

For our benchmark case, we assume the utility function in equation (4). In Section IV we will consider preferences with more curvature over consumption and relax the additive separability with leisure, but this simpler specification turns out to be conservative and yields clean, easily-interpreted closed-form solutions. Because of additive utility over log consumption plus an intercept and a leisure term, we get

$$(10) \quad U_{us}(\lambda_i) = \sum_{a=1}^{100} \beta^a S_a^{us} [u_a^{us} + \log(\lambda_i)],$$

where

$$(11) \quad u_a^{us} \equiv \bar{u} + ga + \sum_{j=1}^{N_a^{us}} \bar{\omega}_{ja}^{us} [\log(c_{ja}^{us}) + v(\ell_{ja}^{us})].$$

We can then solve for the scaling of consumption that equates expected utility in the United States and country i ,

$$(12) \quad \log(\lambda_i) = \frac{1}{\sum_a \beta^a S_a^{us}} \sum_a \beta^a [(S_a^i - S_a^{us})u_a^i + S_a^{us}(u_a^i - u_a^{us})].$$

Rawls requires compensation to move from the United States to country i to the extent that survival rates are higher in the United States (multiplied by flow utility in country i) and to the extent that flow utility is higher in the United States.

To ease notation, define lower case survival rates (in levels and differences) as normalized by the sum of US survival rates:⁴

$$(13) \quad s_a^{us} \equiv \frac{\beta^a S_a^{us}}{\sum_a \beta^a S_a^{us}}$$

$$(14) \quad \Delta s_a^i \equiv \frac{\beta^a (S_a^i - S_a^{us})}{\sum_a \beta^a S_a^{us}}.$$

Denote demographically-adjusted average consumption, leisure, utility from consumption, and utility from leisure as

$$(15) \quad \bar{c}_i \equiv \sum_a s_a^{us} \sum_{j=1}^{N_a^i} \bar{\omega}_{ja}^i c_{ja}^i e^{ga}$$

$$(16) \quad \bar{\ell}_i \equiv \sum_a s_a^{us} \sum_{j=1}^{N_a^i} \bar{\omega}_{ja}^i \ell_{ja}^i$$

⁴Here and elsewhere, the sum over ages is from 1 to 100.

$$(17) \quad E \log c_i \equiv \sum_a s_a^{us} \sum_{j=1}^{N_a^i} \bar{\omega}_{ja}^i \log(c_{ja}^i e^{g_a})$$

$$(18) \quad Ev(\ell_i) \equiv \sum_a s_a^{us} \sum_{j=1}^{N_a^i} \bar{\omega}_{ja}^i v(\ell_{ja}^i).$$

Because of additivity in log consumption, we again get an additive decomposition of welfare differences in terms of consumption equivalents:

$$(19) \quad \begin{aligned} \log \frac{\lambda_i}{\tilde{y}_i} &= \sum_a \Delta s_a^i u_a^i && \textit{Life expectancy} \\ &+ \log \bar{c}_i / y_i - \log \bar{c}_{us} / y_{us} && \textit{Consumption share} \\ &+ v(\bar{\ell}_i) - v(\bar{\ell}_{us}) && \textit{Leisure} \\ &+ E \log c_i - \log \bar{c}_i - (E \log c_{us} - \log \bar{c}_{us}) && \textit{Consumption inequality} \\ &+ Ev(\ell_i) - v(\bar{\ell}_i) - (Ev(\ell_{us}) - v(\bar{\ell}_{us})) && \textit{Leisure inequality,} \end{aligned}$$

where $\tilde{y}_i \equiv y_i / y_{us}$. Looking at welfare relative to income simply changes the interpretation of consumption in the decomposition. The consumption term now refers to the *share* of consumption in GDP. A country with a low consumption share will have lower welfare relative to income, other things equal. Of course, if this occurs because the investment rate is high, this will raise welfare in the long run (as long as the economy is below the Golden Rule). Nevertheless, flow utility will be low *relative* to per capita GDP.

D. Equivalent Variation versus Compensating Variation

The welfare metric above is an *equivalent* variation: by what proportion must we adjust Rawls' consumption in the United States so that his welfare equals that in other countries. Alternatively, we could consider a *compensating* variation: by what factor must we increase Rawls' consumption in country *i* to raise welfare there to the US level. Inverting this number gives a compensating variation measure of welfare, λ_i^{cv} . The resulting welfare measure is very similar to the equivalent variation decomposed in equation (19), with one key difference: in the life expectancy term in the first line of the equation, the equivalent variation weights differences in survival probabilities by a country's own flow utility, while the compensating variation weights differences by US flow utility.⁵

This distinction turns out to matter greatly for poor countries. In particular, flow utility in the poorest countries of the world is estimated to be small, so their low life expectancy has a surprisingly small effect on the equivalent variation: flow utility is low, so it makes little difference that people in such a country live for 50 years instead of 80 years. Thus large shortfalls in life expectancy do not change the equivalent variation measure much in very poor countries, which seems extreme.

⁵ Another related difference is that the denominator of Δs_a^i becomes the cumulative discounted survival in the country under consideration, rather than in the United States.

In contrast, the compensating variation values differences in life expectancy using the US flow utility, which is estimated to be large. Such differences then have a substantial effect on consumption-equivalent welfare. For our benchmark measure, we take a conservative approach and report the equivalent variation. In the robustness section, we show that the compensating variation strengthens our main results.

E. The Welfare Calculation over Time

Suppose the country i that we are comparing to is not China or France but rather the United States itself in an earlier year. In this case, one can divide by the number of periods, e.g., $T = 2007 - 1980 = 27$, and obtain a growth rate of the consumption equivalent. And of course we can do this for any country, not just the United States:

$$(20) \quad g_i \equiv -\frac{1}{T} \log \lambda_i.$$

This growth rate can similarly be decomposed into terms reflecting changes in life expectancy, consumption, leisure, and inequality, as in equation (19).⁶

II. Micro Data and Calibration

To calculate consumption-equivalent welfare, we use household survey data from the United States, Brazil, China, France, India, Indonesia, Italy, Malawi, Mexico, Russia, South Africa, Spain, and the United Kingdom. See Table 1 for a list of the datasets, years, and sample sizes.⁷ A detailed description of the data and programs used in this paper are available in the online Appendix.

Household surveys enable us to calculate consumption inequality for an arbitrary distribution of consumption instead of assuming (say) a lognormal distribution.⁸ With household-level data we can be more confident that consumption is defined consistently across countries and time. For every country, we exclude expenditures on durable goods and focus on nondurables and services (including rent and owner-occupied housing among services).⁹

The micro data we use report the age composition of each household. We allocate consumption equally to each household member. We can take into account household size and age composition in a way that publicly-available Gini coefficients do not.

Our household surveys include hours worked for adults and older children in the household. For the children below the age covered in the survey, we assume zero hours worked. Importantly, the surveys ask about time spent in self-employment,

⁶The issue of equivalent versus compensating variation arises in the growth rate too. Treating 2007 as the benchmark—an equivalent variation—means that the percentage change in life expectancy gets weighted by the flow utility in 1980. Treating 1980 as the benchmark—a compensating variation—weights the percentage change in life expectancy by flow utility in 2007. We average the equivalent and compensating variations for growth rates, as is common practice in the literature.

⁷Krueger et al. (2010) describe an impressive set of recent papers tracking inequality in earnings, consumption, income, and wealth over time in 10 countries. We use the cleaned datasets they made available for Italy, Russia, Spain, and the United States.

⁸Top-coding does not occur for consumption in our countries other than the United States. It arises infrequently in the US data when durables are excluded.

⁹In principle we would like to include the service flow from the stock of durable goods. But most household surveys cover only lumpy durable expenditures rather than household stocks of durable goods.

TABLE 1—HOUSEHOLD SURVEYS

Country	Survey	Year	Number of individuals in the sample
US	CE	2007, 2006, 2005	14,870, 32,184, 32,892
		2004, 2003, 2002	34,064, 34,650, 33,474
		2001, 1993, 1984	31,884, 22,449, 23,825
Brazil	POF/PNAD	2008	189,752 (cons.) and 373,099 (leisure)
		2003	182,036 (cons.) and 370,491 (leisure)
China	CHIP	2002	58,160
France	BDF	2005 and 1984	25,361 and 33,225
India	NSS	2004–2005	602,518
		1983–1984	316,061 (cons.) and 622,912 (leisure)
Indonesia	SUSENAS	2006 and 1993	1,107,594 and 290,763
Italy	SHIW	2006 and 1987	19,407 and 24,970
Malawi	IHS	2004	50,822
Mexico	ENIGH	2006 and 1984	83,559 and 23,985
Russia	RLMS	2007 and 1998	9,784 and 8,998
South Africa	HIS	1993	38,749
Spain	ECPF/ECPH	2001	24,905 (cons.) and 13,985 (leisure)
UK	FES	2005 and 1985	10,289 and 13,465

including subsistence agriculture. We calculate leisure as $(5,840 - \text{hours worked in the year})/5,840$, where $5,840 = 16 \text{ hours a day} \times 365 \text{ days}$.¹⁰

As with consumption, having leisure by age allows us to deal with differences in the age composition of the population across countries and time. Moreover, we can estimate the welfare cost of leisure inequality, just as we estimate the welfare cost of consumption inequality (again using the observed distribution).

From behind the Rawlsian veil, consumption and leisure interact with mortality to determine expected utility. We combine data from household surveys with mortality rates by age from the World Health Organization.¹¹

A. Summary Statistics from the Micro Data

This section aggregates our underlying micro data in various ways to shed light on the components of our welfare calculation.

¹⁰For countries such as the United States, we have weeks worked per year as well as hours worked per week. For most countries, however, the household surveys only cover hours per week, so we draw on OECD and other sources for weeks worked per worker. See the online Appendix.

¹¹See <http://apps.who.int/gho/data/node.main.692> (accessed July 25, 2013). We use data from 1990, 2000, and 2011, interpolating to get needed years in between. For the very poorest countries, the adult mortality rates are inferred from child mortality rates. See http://www.who.int/whr/2006/annex/06_annex1_en.pdf for “uncertainty ranges” associated with WHO mortality rates.

FIGURE 1. WITHIN-COUNTRY INEQUALITY

Notes: The standard deviation of log consumption within each economy is measured from the household surveys listed in Table 1. We use survey-specific sampling weights and US survival rates across ages using an analog of equation (17), with no discounting or growth.

Consumption.—Figure 1 reports the standard deviation of log consumption across people in our household survey countries. We divide household expenditures equally across people in each household, and add per capita government consumption in the same year from the Penn World Tables 8.0 (Feenstra, Inklaar, and Timmer 2015). We use sampling weights and discount using US survival rates by age, analogous to the way we construct the mean of log consumption in equation (17). The resulting inequality is highest in South Africa, Brazil, and Mexico. Inequality is lower in France, Italy, and the United Kingdom than in the United States.

Leisure.—Figure 2 summarizes annual hours worked per person in our household surveys. Figure 3 reports the standard deviation across people of annual hours worked.¹² Hours worked are substantially lower in France, Italy, Spain, and the United Kingdom than in the United States, as has been widely noted. More novel, *inequality* of hours worked is lower in these same countries than in the United States.

Mortality Rates.—Figure 4 presents life expectancy in years from the World Health Organization for our baseline household survey years. It ranges from 50 in Malawi, the poorest country, to above 75 in the richest countries.

B. Calibration

To implement our welfare calculations, we need to specify the baseline utility function. (In Section IV we will explore a range of robustness checks to our choices

¹²Parente, Rogerson, and Wright (2000) argue that barriers to capital accumulation explain some of the variation in market hours worked. Like us, they emphasize that the gain in home production can partially offset the loss in market output. Prescott (2004) attributes some of the OECD differences in hours worked to differences in tax rates, as do Ohanian, Raffo, and Rogerson (2008).

FIGURE 2. ANNUAL HOURS WORKED ACROSS COUNTRIES

Notes: The measure shown here of annual hours worked per capita is computed from the household surveys noted in Table 1, using survey-specific sampling weights and US survival rates across ages as in equation (16), with no time discounting.

FIGURE 3. INEQUALITY IN ANNUAL HOURS WORKED

Note: See notes to Figure 2.

here.) Following the macro literature, we assume utility from leisure takes a form that implies a constant Frisch elasticity of labor supply (that is, holding the marginal utility of consumption fixed, the elasticity of labor supply with respect to the wage is constant). Since labor supply in our setting is $1 - \ell$, in terms of the utility function in equation (4) this gives $v(\ell) = -\frac{\theta\epsilon}{1+\epsilon}(1 - \ell)^{\frac{1+\epsilon}{\epsilon}}$, where ϵ denotes the Frisch elasticity. This leaves five parameters to be calibrated: the growth rate g , the

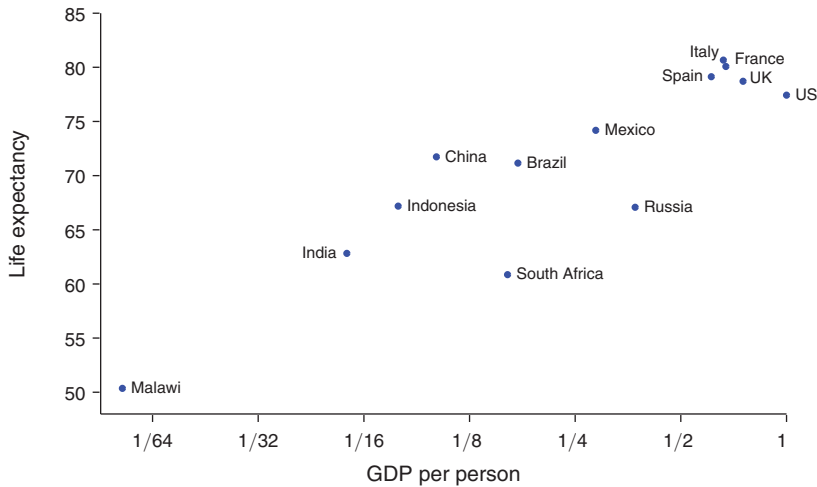

FIGURE 4. LIFE EXPECTANCY

Note: Life expectancy at birth in each country is measured as the sum over all ages of the probability of surviving to each age, using life tables from the World Health Organization.

discount factor β , the Frisch elasticity ϵ , the utility weight on leisure or home production θ , and the intercept in flow utility \bar{u} .

We choose a common growth rate of 2 percent per year. An alternative would be to try to forecast future growth rates for each country, but such forecasts would have very large standard errors, particularly since we would need forecasts for every year over the next century. With an annual real interest rate of 4 percent in mind, we set the discount factor to $\beta = 0.99$. Recall that there is already additional discounting inherent in the expected utility calculation because of mortality. A 4 percent real interest rate is consistent with the standard Euler equation with log preferences, 2 percent consumption growth, roughly 1 percent discounting for mortality, and 1 percent from the discount factor.

Surveying evidence such as Pistaferri (2003), Hall (2009a, b) suggests a benchmark value for the Frisch elasticity of 0.7 for the intensive (hours) margin and 1.9 for the extensive and intensive margins combined. Chetty (2012) reconciles micro and macro estimates of the Frisch elasticity and recommends a value of 0.5 or 0.6 for the intensive margin. We consider a Frisch elasticity of 1.0 for our benchmark calibration, which implies that the disutility from working rises with the square of the number of hours worked. As we discuss in the robustness section, the results are not sensitive to this choice.

To get the weight on the disutility from working, θ , recall that the first-order condition for the labor-leisure decision is $u_\ell/u_c = w(1 - \tau)$, where w is the real wage and τ is the marginal tax rate on labor income. Our functional forms then imply $\theta = w(1 - \tau)(1 - \ell)^{-1/\epsilon}/c$. For our benchmark calibration, we assume this first-order condition holds for the average prime-age worker (25–55 years old) in the US Consumer Expenditure Survey (CE) in 2006. We take the marginal tax rate in the United States from Barro and Redlick (2011), who report a value of 0.353 for 2006. Taking into account the ratio of earnings to consumption and average leisure

among 25–55-year-olds of $\ell_{us} = 0.656$ in the CE, we arrive at $\theta = 14.2$.¹³ Note that we only assume the “average” US worker is equating their marginal rate of substitution between consumption and leisure and their real after-tax wage. We are implicitly invoking wedges (e.g., labor market frictions) to explain deviations from this static first order condition for individuals within the United States and in other countries. We leave it for future research to explore the role of preference heterogeneity versus wedges.

Calibration of the intercept in flow utility, \bar{u} , is less familiar. This parameter is critical for valuing differences in mortality. We choose \bar{u} so that a 40-year-old, facing the consumption and leisure uncertainty in the 2006 US distribution, has a value of remaining life equal to \$6 million in 2007 prices.¹⁴ In their survey of the literature, Viscusi and Aldy (2003) recommend values in the range of \$5.5–\$7.5 million. Murphy and Topel (2006) choose a value of around \$6 million. Our baseline value of \$6 million is broadly consistent with this literature. This choice leads to $\bar{u} = 5.00$ when aggregate consumption per capita in the United States is normalized to 1 in 2007. With these preferences, the implied value of life will be substantially lower in poor countries; see Kremer et al. (2011) for evidence consistent with this implication. Wider evidence on the value of life in developing countries is admittedly scant.

III. Welfare across Countries and over Time

We begin with levels of consumption-equivalent welfare for the 13 countries for which we have detailed micro data. The calculation is based on equation (19), implemented for the most recent year we have household survey data and with Penn World Tables 8.0 data on consumption and income. Our first finding can be summarized as follows:

KEY POINT 1: *GDP per person is an excellent indicator of welfare across the broad range of countries: the two measures have a correlation of 0.98. Nevertheless, for any given country, the difference between the two measures can be important. Across 13 countries, the median deviation is about 35 percent.*

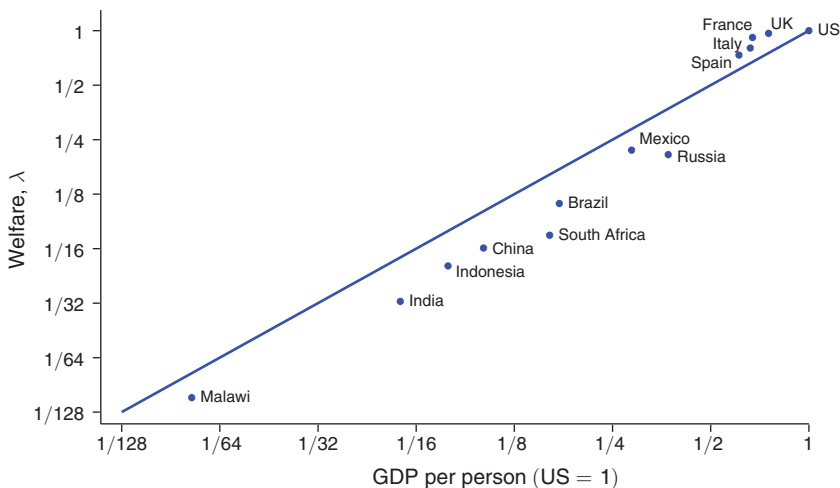

Figure 5 illustrates this first point. The top panel plots the welfare measure, λ , against GDP per person. What emerges prominently is that the two measures are highly correlated, with a correlation coefficient (for the logs) of 0.98. Thus per capita GDP is a good proxy for welfare under our assumptions. At the same time, there are clear departures from the 45-degree line. In particular, many countries with very low GDP per capita exhibit even lower welfare. As a result, welfare is more dispersed (standard deviation of 1.51 in logs) than is income (standard deviation of 1.27 in logs).

The bottom panel provides a closer look at the deviations. This figure plots the ratio of welfare to per capita GDP across countries. The European countries have

¹³We scale up CE consumption expenditures in three ways. First, we add in durables expenditures in 2006, to approximate their flow value. Second, we take into account that CE expenditures were only 61.9 percent of NIPA consumption in that year. Third, we scale up consumption by the ratio of (private plus public consumption)/(private consumption) for the United States in 2006 in the Penn World Tables 8.0.

¹⁴For this computation, we use the same data and parameters that we use later in the paper to compute λ . For example, we discount the future at rate $\beta = 0.99$ and allow consumption to grow at 2 percent per year.

Panel A. Welfare and income are highly correlated at 0.98

Panel B. But this masks substantial variation in the ratio of λ to GDP per capita

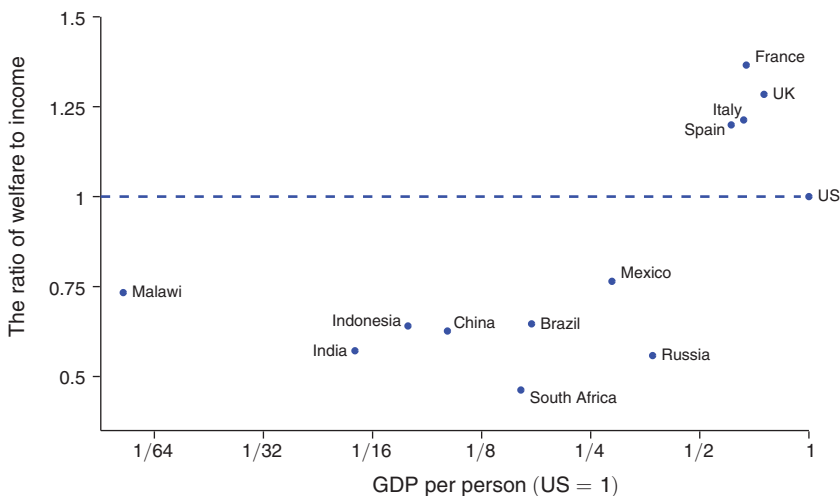

FIGURE 5. WELFARE AND INCOME ACROSS COUNTRIES

welfare measures 22 percent higher than their incomes. The remaining countries, in contrast, have welfare levels that are typically 25 to 50 percent below their incomes. The way to reconcile these large deviations with the high correlation between welfare and income is that the “scales” are so different. Incomes vary by more than a factor of 64 in our sample, i.e., 6,300 percent, whereas the deviations are on the order of 25 to 50 percent.

KEY POINT 2: *Average Western European living standards appear much closer to those in the United States when we take into account Europe’s longer life expectancy, additional leisure time, and lower levels of inequality.*

Table 2 provides a closer look at the welfare decomposition based on (19). The United Kingdom, France, Italy, and Spain all have per capita incomes around 2/3 that in the United States. Consumption-equivalent welfare is about 22 log points higher, averaging 85 percent of that in the United States.

Consider the case of France. Income in France is 67 percent of the US level. Longer life expectancy, additional leisure, and lower inequality of consumption and leisure each boost welfare. Taken together, consumption-equivalent welfare is more than 90 percent of the US level. The italic numbers in the table help to make sense of this difference. Mortality rates are significantly lower in France than in the United States. Life expectancy is 80.1 years in France versus 77.4 years in the United States. This difference adds 15 log points to welfare. With respect to leisure, average annual hours worked per capita in the United States are 877 versus only 535 in France. The implied difference in leisure adds 8 log points to welfare.

Next, consider consumption inequality. The standard deviation of log consumption in the French micro data is 0.422 versus 0.538 in the United States. To see how this affects welfare, consider a hypothetical in which consumption is lognormally distributed. In this case, lower inequality adds $0.5(0.538^2 - 0.422^2) = 0.056$, or 5.6 percent, to welfare. Without imposing the lognormal approximation we get 10.2 log points. Interestingly, with our additively separable preferences and behind-the-veil approach, it does not matter to our calculation whether consumption inequality is permanent from birth or i.i.d. at each age. Rawls values the consumption uncertainty in exactly the same way.

Finally, consider leisure inequality. Our baseline preferences specify a Frisch elasticity of labor supply of one, which implies a disutility from working that depends on the square of annual hours worked. The standard deviation of annual hours per capita is 1,091 in the United States versus 747 in France. With convex costs of working, this heterogeneity adds 12 log points to welfare in France. One can combine this number with the consumption inequality number to say that lower inequality raises welfare in France relative to the United States by more than 20 log points.

The exact numbers, either for France or for the other European countries, depend on the specific assumptions we make. As we will show later, however, the general point that welfare in Western Europe is much closer to US levels than income comparisons suggest is quite robust.

KEY POINT 3: *Many developing countries, including all eight of the non-European countries in our sample, are poorer than incomes suggest because of a combination of shorter lives, low consumption shares, and extreme inequality.*

The country details are reported in the lower half of Table 2. The same story appears repeatedly. A life expectancy of only 67 years cuts Russia's welfare by 50 log points, or around 40 percent. South Africa's high mortality leads to a life expectancy of 61 years in 1993 (even lower by 2007 we'll see later), which reduces welfare by 55 log points. Interestingly, the even lower life expectancy in Malawi of 50 years only reduces welfare there by 39 log points. Why the difference?

As can be seen in equation (19) or (7), the loss from low life expectancy is weighted by the value of flow utility—the utility lost from living one year less. Malawi is much poorer than South Africa, so its shortfall in life expectancy is

Notes: The table shows the consumption-equivalent welfare calculation based on equation (19). See Table 1 for sources and years. The second line for each country shows life expectancy, the ratio of consumption to income, annual hours worked per capita, the standard deviation of log consumption, and the standard deviation of annual hours worked, all computed from the cross-sectional micro data, with no discounting or growth.

penalized less.¹⁵ As we will show, this is a key place where the equivalent variation differs from the compensating variation. The compensating variation weights differences in mortality by US flow utility. In the robustness section, we'll see this leads to much larger welfare differences.

A second reason that welfare is lower than income in several countries is that average consumption—as a share of income—is low relative to the United States. Utility depends on consumption, not income. Of course, an offsetting effect is that the low consumption share may raise consumption in the future. To the extent that countries are close to their steady states, this force is already incorporated in our calculation. However, in countries with upward trends in their investment rates, our calculation will understate steady-state welfare. China is an obvious candidate for this qualification, though correcting for this has a modest effect.¹⁶

¹⁵ Table A3 in the online Appendix reports the implied value of life in each of our 13 countries.

¹⁶ See Table 8 of Jones and Klenow (2010).

High consumption inequality is a final force contributing to lower welfare in many developing countries, with the sharpest examples being Brazil and South Africa. Consumption inequality in Brazil reduces welfare by 21 percent and in South Africa by 28 percent. In contrast, the effects of leisure and leisure inequality are relatively small in developing countries: annual hours worked per person and its heterogeneity are similar to levels in the United States.

A. Growth Rates

We turn now to welfare growth over time. Rather than comparing Rawls' expected utility from living in the United States versus another country in the same year, we now consider how Rawls might value living in the same country at two different points in time. The decomposition in equation (19) remains valid, only we now express it in growth rate terms as in (20). We begin with a point that summarizes the differences between welfare growth and growth in per capita GDP:

KEY POINT 4: *Welfare growth averages 3.1 percent between the 1980s and mid-2000s, versus income growth of 2.1 percent, across the seven countries for which we have household surveys during these periods. A boost from rising life expectancy of about 1 percentage point per year accounts for the difference.*

Figure 6 documents a high correlation (0.97) between welfare growth and income growth across our micro dataset countries. Russia is an obvious outlier—our household survey years of 1998 and 2007 correspond to a period of rapid Russian growth. The lower panel of the figure shows that the typical country gains about a percentage point of growth when shifting from income to welfare. Growing at 3 percent instead of 2 percent per year, living standards double in 24 years instead of 36 years; over a century, this leads to a 20-fold increase rather than a 7-fold increase.

The source of the gain is evident in Table 3. As shown in the last row of the table, the bulk of the gain for the average country results from the life expectancy term. Living standards are rising mostly because of rising consumption per year of life. But the fact that we can enjoy our consumption over a longer lifetime is also important. Our finding that rising life expectancy contributed importantly to welfare growth has at least two antecedents in the literature. Nordhaus (2003) offered a back-of-the-envelope calculation suggesting that rising life expectancy over the twentieth century was as important to welfare as consumption growth. Our calculation using micro data for a range of countries supports the tenor of Nordhaus's calculation, though our estimate is closer to one-half. Becker, Philipson, and Soares (2005) calculated that rising life expectancy from 1960–2000 raised full income growth about 1.7 percentage points per year for the poorest 50 countries, versus 0.4 percentage points per year for the 50 richest countries. In our more recent (but much smaller) sample of nine countries, we find that rising life expectancy raised welfare growth by a little over one percentage point per year on average in five OECD countries and four non-OECD countries alike.

The details of specific countries lead to additional insights. Falling leisure and rising inequality have reduced growth by roughly half a percentage point in the United States, Italy, and Mexico. For example, in the United States annual hours worked per

Panel A. The correlation between welfare growth and income growth is 0.97

Panel B. The median absolute value of the difference between welfare and income growth is 0.95 percentage points

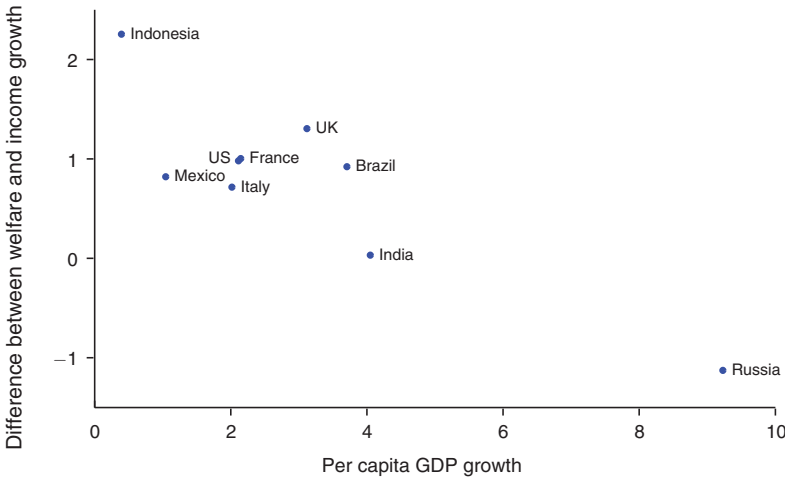

FIGURE 6. WELFARE AND INCOME GROWTH (Percent)

person rose from 810 to 889 between 1984 and 2006. We estimate that this falling leisure reduced consumption-equivalent welfare growth by about a tenth of a percentage point per year. According to the CE, consumption inequality rose, reducing growth by another 24 basis points.¹⁷ Finally, rising leisure inequality reduces US welfare growth another 8 basis points. Taken together, these three channels reduce consumption-equivalent welfare growth in the United States by 42 basis points per year.

Mexico and Italy exhibit similar patterns. Falling leisure reduces welfare growth by 0.17 percentage points per year in Italy and 0.23 percentage points per year in

¹⁷The CE displays a relatively small increase in consumption inequality, as emphasized by Krueger and Perri (2006). According to Aguiar and Bils (2015), savings and Engel curves in the CE suggest that consumption inequality rose as much as income inequality in the United States over this period.

TABLE 3—WELFARE GROWTH

Average*	3.14	2.13	1.02	1.15	0.11	−0.05	−0.16	−0.04

Notes: The table shows a decomposition for average annual consumption-equivalent welfare growth based on equation (20). Years are shown in parentheses. Average denotes the average across the nine countries, while Average* excludes Russia and Brazil. The second line for each country displays the raw data on life expectancy, the ratio of consumption to income, annual hours worked per capita, the standard deviation of log consumption, and the standard deviation of annual hours worked, for the start and ending year, computed with no discounting or growth.

Mexico. Rising consumption and leisure inequality, combined, reduce growth by 0.46 and 0.30 percentage points per year in Italy and Mexico. The sum of these three forces is therefore about 0.63 percentage points per year in Italy and 0.53 percentage points per year in Mexico.

IV. Robustness

Here we gauge robustness to alternative assumptions, such as about the utility function. Table 4 shows that the gap we find between welfare and income is quite robust. More detailed results—including decompositions for France, China, and Indonesia—are available in the online Appendix.

The second row of Table 4 indicates that, if we do not discount or incorporate growth, the differences between welfare and income are somewhat smaller than in the baseline case (median absolute deviation between welfare and income of 30 percent rather than 35 percent). The reason is that life expectancy differences are less important if consumption is not growing over the life cycle (a bigger effect at 2 percent per year than the pure time discounting of 1 percent per year). If we retain growth but discount time more heavily at 4 percent per year rather than 1 percent per year, as shown in the third row, the median gap between welfare and income shrinks a little further to 28 percent.

TABLE 4—ROBUSTNESS RESULTS

	Welfare levels			Welfare growth

Notes: See main text for discussion of the various robustness cases. “Median AbsDev” denotes the median absolute deviation of λ_i/\bar{y}_i from 100 percent in the levels case and $g_\lambda - g_y$ in the growth rate case. Footnote (a): The sample size changes when we move to the CRRA/CFE preferences. In particular, we require both consumption and leisure to come from the same household survey, which rules out Brazil and Spain (and India for growth). Also, countries for which the growth rate starts before 1990 use the 1990 mortality rates in the initial year with no correction in the CRRA/CFE case (the numbers are scaled to reflect the changing years in the log case, where the terms can be separated additively). The case of $\gamma = 1$ and $\underline{c} = 0$ is reported separately here to reflect the changing sample size and treatment of mortality growth (otherwise, it is identical to the benchmark case).

In our baseline we spread household consumption evenly across household members. The fourth row of Table 4 shows that it would make little difference if we instead set individual consumption equal to household consumption divided by the *square root* of the number of individuals in the household, as in the OECD’s equivalence scale.

The deviation between welfare and income is more modest if we evaluate utility only for those age 2 and older; differences in infant mortality matter, but do not drive the results. Evaluating expected utility only for those age 40 and older has little effect on level comparisons, but widens the growth rate differences (from a median of 1.0 percent to 1.6 percent per year).

In our baseline case, we assume kids enjoy 100 percent leisure time. An alternative is to assume kids’ leisure is the same as adults’ leisure, on average. When we base leisure on hours worked per adult rather than per person (the row titled “Kids get adult leisure”), it has little effect on the typical deviation between welfare and income in levels. It does narrow the difference between welfare and income growth rates from 1.0 percent to 0.8 percent per year.

A. Equivalent Variation and Compensating Variation

Recall that our benchmark results are based on equivalent variations (EV). Table 4 indicates that the median gap between welfare and income relative to the United States is 44 percent if we use compensating variations (CV), compared to the 35 percent we get in the baseline with EV.

As discussed in Section I, the distinction between EV and CV rests primarily on whether differences in life expectancy are valued using a country's own flow utility (for EV) or the US flow utility (for CV). For rich countries, this makes little difference. Even for a country with moderate income, like China, the differences are relatively small. The difference between EV and CV is more apparent for extremely poor countries. Consider Malawi. Our EV-based welfare ratio for the United States versus Malawi, which weights Malawi's lower life expectancy by its own utility flow, is 106 (i.e., over 100 times the consumption-equivalent welfare in the United States as in Malawi). The CV-based welfare ratio, which uses US flow utility to value the shortfall in Malawi's life expectancy, is comparatively enormous at 796.

B. Alternative Utility Specifications

Our benchmark utility function adds log consumption, a leisure term, and an intercept. This yields an additive decomposition of welfare differences. Now consider a more general utility function with non-separable preferences over consumption and leisure:

$$(21) \quad u(C, \ell) = \bar{u} + \frac{(C + \underline{c})^{1-\gamma}}{1-\gamma} \left(1 + (\gamma - 1) \frac{\theta\epsilon}{1+\epsilon} (1 - \ell)^{\frac{1+\epsilon}{\epsilon}} \right)^\gamma - \frac{1}{1-\gamma}.$$

This functional form reduces to our baseline specification when $\gamma = 1$ and $c = 0$.

When $c = 0$, this is the “constant Frisch elasticity” functional form advocated by Shimer (2009) and Trabandt and Uhlig (2011). The parameter ϵ is the constant Frisch elasticity of labor supply (the elasticity of time spent working with respect to the real wage, holding fixed the marginal utility of consumption).

Several cases in Table 4 impose more curvature over consumption than in the log case. With $\gamma = 1.5$ —and $\underline{c} = 0.05$ to prevent Rawls from preferring death to life in poor countries like Malawi—the median absolute percentage deviation of welfare from income rises a little, and the growth deviation falls somewhat.¹⁸ Consumption inequality is more costly to Rawls with $\gamma = 1.5$ than in our baseline of $\gamma = 1$. The next row of Table 4 increases curvature further to $\gamma = 2$, while at the same time boosting the intercept to $\underline{c} = 0.20$. The median gap between welfare and income becomes notably wider at 45 percent.

When $\gamma > 1$, leisure and consumption are substitutes. As stressed by Hall (2009b), such substitutability is consistent with evidence that market consumption falls upon retirement. Having consumption and leisure be substitutes boosts welfare in (for example) France relative to the United States, since consumption and leisure inequality are both higher in the United States *and* negatively correlated across individuals in the United States. If consumption and leisure were instead complements, the greater inequality in the United States would be less costly.

¹⁸ Even with log utility, it is conceivable for expected lifetime utility to be negative if consumption is sufficiently low. In our baseline case, this does not occur for any country, and in fact expected flow utility at each age is also positive in all countries. When we boost γ above one, however, this is no longer true. We pick a “round” value for c that ensures that all countries (with Malawi being the most binding case) have positive expected lifetime utility.

We next consider a higher weight on leisure versus consumption in utility. As in the baseline we have $\gamma = 1$ and $\underline{c} = 0$, but we now increase the value of θ . In particular, we choose θ to rationalize the choice of higher average leisure in France than in the United States. Increasing the importance of leisure in this way makes little difference.¹⁹

Toward the end of Table 4, we consider alternative values for the Frisch elasticity of labor supply: 0.5 from Chetty (2012) or 2.0 at the upper end of Hall's (2009b) recommended range. These changes, too, have little effect on our results.

Our final robustness check is to change the intercept in the utility function. We set the intercept so that the remaining value of life for a 40-year-old in the United States in 2005 dollars is \$5 million or \$7 million rather than the baseline value of \$6 million. With a value of life of \$5 million in the United States, the intercept in the utility function falls. Life is worth less in all countries, so differences in life expectancy play a smaller role. This reduces the welfare gain from higher longevity in European countries like France and mitigates the welfare loss from low lifespan in developing countries like China. Overall, the median deviation between welfare and income falls from our benchmark value of 35 percent to a smaller but still substantial 30 percent.

With a US value of life of \$7 million, the contrast between welfare and income is sharper. The deviation between welfare and income rises to almost 40 percent rather than 35 percent in levels, and to 1.1 percent per year rather than 1.0 percent per year in 1980–2007 growth rates. With more utility from a year of life, differences in the levels and growth rates of life expectancy naturally matter more.

V. Measuring Welfare for a Broad Range of Countries

We now calculate consumption-equivalent welfare for a broader set of countries and years. The caveat is that much stronger assumptions are required because of data limitations; these calculations are based on the “illustrative example” given at the start of the paper in equation (7). We assume consumption is lognormally distributed and is independent of age. We assume $\beta = 1$ and $g = 0$ so that survival rates can be summarized by a single statistic—life expectancy, which is widely available. We will refer to this as a “macro” calculation, as it relies on publicly-available multi-country datasets instead of micro data from household surveys.

The data sources for the macro calculation are discussed in detail in our online Appendix. Briefly, we use the Penn World Table 8.0 to measure income, consumption, employment, and population. This source also provides hours worked for 52 (mostly rich) countries. We use the UNU-WIDER World Income Inequality Database, Version 3.0a, which is itself a summary of micro surveys, to measure consumption inequality; this database reports Gini coefficients which we convert to the standard deviation of log consumption under the assumption of log normality.²⁰ Finally, life expectancy is from the World Bank's HNPStats database.²¹

¹⁹ As mentioned earlier, a topic for future research would be exploring the role of preference heterogeneity versus wedges in explaining the joint consumption and hours decisions across households across and within countries.

²⁰ Consumption inequality data are directly available for 68 (mostly developing) countries. For 49 (mostly rich) countries, we infer consumption inequality from inequality in disposable income. When inequality data are not available, we assign a zero value to the contribution of inequality in our accounting exercise.

²¹ <http://datatopics.worldbank.org/hnp/>.

A. Comparing Results Using Macro and Micro Data

To begin, we assess the accuracy of our macro calculations by comparing them to the detailed micro results we reported earlier. Table 5 shows the comparison, where we match the macro calculation to the same year used in the micro calculation.

The correlation of $\log \lambda$ (computed for the same year) using macro and micro data is 0.999. The mean log deviation between the two measures is 0.0007, while the mean *absolute* log deviation is 0.0674. Thus on average the macro calculation seems to work quite well, and the average deviation between the two measures is about 6.7 percent, much of it explained by the absence of leisure inequality from our macro calculation.

This evidence suggests that calculations using publicly-available multi-country datasets are potentially informative. With this motivation, the remainder of this section considers welfare calculations for a broad set of countries using the “macro” approach.

B. Results for a Broad Set of Countries

Figure 7 provides an overview of welfare across countries using the macro data. The top panel plots the welfare measure, λ , against GDP per person for the year 2007—both relative to the United States. As in the micro results, the two measures are very highly correlated, with a correlation (in logs) above 0.95. At the same time, there are clear departures from the 45-degree line.

Table 6 summarizes the macro welfare comparisons, which reinforce the key points from the micro data. First, Western Europe is much closer to the United States in welfare than in income: income levels are about 73 percent of the United States, while consumption-equivalent welfare averages 82 percent. Higher life expectancy in Western Europe adds about 13 percent to welfare on average, higher leisure adds 3 percent, and lower consumption inequality adds 8 percent.

Other regions exhibit the opposite pattern: welfare is systematically lower than income. Lower life expectancy reduces their welfare between 16 and 46 percent. Higher consumption inequality in sub-Saharan Africa and Latin America reduce their welfare around 10 and 16 percent, respectively. Finally, low consumption shares play an important role in Western Europe and Coastal Asia, reducing welfare by 13 and 28 percent.

The macro data allows us to look at many more countries. Missing data is sometimes a problem, most often for annual hours per worker and consumption inequality. In these cases, we assign US values to the missing observations so that no correction to the income measure is made. Table 7 shows welfare levels for a selection of countries in 2007.²²

OECD.—The key point we made regarding Western Europe shows up for France, Sweden, Germany, and Japan: all have higher welfare than their incomes suggest, largely due to higher life expectancy, higher leisure, and lower consumption inequality. Norway stands out as an interesting exception. It receives the usual

²²Results for our complete sample of 152 countries are available at <http://www.stanford.edu/~chadj/BeyondGDP500.xls>.

Notes: The first row for each country reports the welfare decomposition obtained using our macro data sources. The second row repeats the micro results provided earlier. The year varies by country and corresponds to the latest year for which we have household survey data.

positive contributions from these “European” forces. However, these effects are more than offset by Norway’s extremely low consumption share. This is readily understood in the context of the North Sea oil discovery: Norway is consuming much less than its current income to smooth the oil revenues into the future. Ireland shows a related pattern, with its high investment rate and low consumption share.

East Asia.—Differences between welfare and income are also quite stark for East Asia. According to GDP per person, Singapore and Hong Kong are rich countries on par with the United States. The welfare measure substantially alters this picture. Singapore declines dramatically, from an income 117 percent of the United States to a welfare of just half that at 57 percent. A sizable decline also occurs for South Korea, from 58 percent for income to 45 percent for welfare. Both countries, and Japan as well, see their welfare limited sharply by low consumption shares. This force is largest for Singapore, where the consumption share of GDP is below 0.5. This is the levels analogue of Alwyn Young’s (1992) growth accounting point. Singapore exhibits a very high investment rate in recent decades. This capital accumulation raises income and consumption in the long run, but the effect on consumption is less than the effect on income, which reduces the welfare-to-income ratio. Leisure is

Notes: log ratio denotes the log of the ratio of λ to per capita GDP (US = 100). The decomposition applies to this ratio; that is, it is based on equation (7). The log ratio is the sum of the last four terms in the table: the life expectancy effect, the consumption share of GDP, leisure, and inequality. (Of course, the sum does not hold for the median absolute deviation or the standard deviation.) Sample size is 152 countries, and regional averages are population weighted.

has dramatically reduced their life expectancy to around 52 years, lowering welfare by more than 85 log points in these countries. Inequality in both countries is also among the highest in the world, with a standard deviation of log consumption of more than 1.0—reducing welfare by more than 33 log points. The combined effect of these changes is to push welfare substantially below income: both countries have welfare below 5 percent of that in the United States, placing them in the middle of the pack of poor economies.

C. Growth Rates

Table 8 reports summary statistics for welfare growth. These statistics enhance our understanding of Key Point 4 above regarding life expectancy and growth. Western Europe, the United States, and Latin America all exhibit welfare growth a full percentage point higher than income growth between 1980 and 2007. The key driving force behind this faster growth is rising life expectancy, which adds about 1.3 percentage points to growth in Europe and Latin America and around 0.8 percentage points in the United States and Coastal Asia. Tragically, sub-Saharan Africa has experienced a much smaller boost (0.3 percentage points), as discussed further below.

Table 9 and Figure 8 illustrate how welfare growth differs from income growth for select countries. Some of the major highlights:

Japan.—Despite its “lost decade” after 1990, Japan moves sharply up in the growth rankings when considering welfare instead of income. Between 1980 and 2007, income growth in both the United States and Japan averaged just over 2.0 percent per year. But rising life expectancy, rising consumption relative to GDP, and rising leisure nearly double Japan’s welfare growth to 4.0 percent per year, almost a full percentage point faster than US welfare growth of 3.1 percent over this period.

TABLE 7—WELFARE ACROSS COUNTRIES IN 2007: MACRO DATA

Notes: The table shows the consumption-equivalent welfare calculation based on equation (7). The second line for each country shows life expectancy, the ratio of consumption to income, annual hours worked per capita, and the standard deviation of log consumption. Results for additional countries can be downloaded at <http://www.stanford.edu/~chadj/BeyondGDP500.xls>.

AIDS in Africa.—Young (2005) pointed out that AIDS was a humanitarian tragedy in Africa, but that it might boost GDP per worker by raising capital per worker. Our welfare measure provides one way of adding these two components together to measure the net cost. As Young suspected, the net cost proves to be substantial. Botswana loses the equivalent of 1.1 percentage points of consumption growth from seeing its life expectancy fall from 60.5 to 52.1 years, similar to the loss in South Africa. Botswana's growth rate falls from one of the fastest in the world at 6.27 percent to the much more modest 2.94 percent. Already poor, sub-Saharan Africa falls

Notes: Average annual growth rates. The decomposition applies to the “Difference,” that is, to the difference between the first two data columns. Sample size is 128 countries, and regional averages are population weighted.

further behind the richest countries from 1980 to 2007, and more so for welfare than for income.

The New “Singapore.”—An important contributor to growth in GDP per person in many rapidly-growing countries is factor accumulation: increases in investment rates and in hours worked. This point was emphasized by Young (1992) in his study of Hong Kong and Singapore. Yet this growth comes at the expense of current consumption and leisure, so growth in GDP provides an incomplete picture.

Table 9 shows that many of the world’s fastest growing countries are like Singapore in this respect. In terms of welfare growth, China, Ireland, Hong Kong, and Botswana all lose more than a full percentage point of annual growth to these channels, while South Korea and India lose more than a half percentage point. These countries remain among the fastest growing countries in the world, however, as these negative effects are countered by large gains in life expectancy.

VI. Conclusion

For a given specification of preferences, we calculate consumption-equivalent welfare for various countries and years using data on consumption, leisure, consumption inequality, leisure inequality, and mortality by age. Our main finding is that cross-country inequality in welfare is even greater than inequality in incomes. More specifically, our findings can be summarized as follows:

First, the correlation between our welfare index and income per capita is very high. This is because average consumption differs so much across countries and is strongly correlated with income. Second, living standards in Western Europe are much closer to those in the United States than it would appear from GDP per capita. Longer lives with more leisure time and more equal consumption in Western Europe largely offset their lower average consumption vis-à-vis the United States. Third, in most developing economies, welfare is markedly lower than income, due primarily to shorter lives but also to more inequality. Finally, economic growth in many countries of the world (the exception being sub-Saharan Africa) is about 50 percent faster than previously appreciated, a boost almost entirely due to declining mortality.

Notes: The second line for each country displays the raw data on life expectancy, the consumption share, annual hours worked per capita, and the standard deviation of log consumption for 1980 and 2007. See notes to Table 8.

Our calculations entail many strong assumptions. We therefore checked and confirmed robustness to alternative welfare measures and alternative utility functions over consumption and leisure. With the requisite data, one could relax more of our assumptions. Mortality by age surely differs within countries (e.g., by education). Preferences over consumption and leisure must differ within countries, perhaps mitigating the welfare cost of unequal outcomes. Where household data is available going back far enough, one could better estimate the present discounted value of welfare.

FIGURE 8. WELFARE AND INCOME GROWTH, 1980–2007 (Percent)

One could carry out similar calculations across geographic regions within countries, or across subgroups of a country's population (e.g., by gender or race). Even more ambitious would be to try to account for some of the many important factors we omitted entirely, such as morbidity, the quality of the natural environment, crime, political freedom, and intergenerational altruism. We hope our simple measure proves to be a useful building block for work in this area.
